Abstract

We study a conjectured connection between AdS/CFT and a real-space quantum renormalization group scheme, the multi-scale entanglement renormalization ansatz (MERA). By making a close contact with the holographic formula of the entanglement entropy, we propose a general definition of the metric in the MERA in the extra holographic direction. The metric is formulated purely in terms of quantum field theoretical data. Using the continuum version of the MERA (cMERA), we calculate this emergent holographic metric explicitly for free scalar boson and free fermions theories, and check that the metric so computed has the properties expected from AdS/CFT. We also discuss the cMERA in a time-dependent background induced by quantum quench and estimate its corresponding metric.

1 Introduction

The holographic principle [1] is a significant idea that relates gravitational theories to those without gravity such as quantum field theories. The AdS/CFT correspondence is the most well-understood example of the holography [2, 3]. On the one hand, it allows us to study strongly coupled quantum systems by using general relativity. At the same, the holographic dictionary, in principle, allows us to analyze quantum aspects of gravity, which have been remaining as one of major challenges in theoretical physics. Our understanding on the basic principle and mechanism of the holography is, however, still limited. To address fundamental issues in quantum gravity, such as the creation of the universe or cosmology, it is highly desirable to develop a more general framework for the holography, which allows us to go beyond the anti de-Sitter spacetime and explore non-trivial generalizations of AdS/CFT.

Recently, an interesting connection between AdS/CFT and a real-space renormalization group scheme in quantum many-body systems, called the multi-scale entanglement renormalization ansatz (MERA) [4, 5], has been pointed out by Swingle [6]. Refer also to [7, 8, 9, 10, 11, 12, 13, 14, 15] for related recent works.

The MERA is originally proposed as an efficient (numerical) method to find a ground state for a given quantum many-body system. A very brute-brash illustration of the basic construction of the MERA may be given as follows. (See the main text for more details.) Suppose we want to find a ground state for an interacting spin system on a one-dimensional lattice with 2^m sites. To deal with the exponentially large Hilbert space, we develop an iterative procedure; starting from the true ground state with 2^m spins, at each step of iteration, we look for a description in terms of fewer effective, degrees of freedom, by coarse-graining the original spins. In order for this “naive” application of the real space renormalization group idea to work for quantum systems, however, quantum correlation between different spins need to be taken care of. In the MERA the coarse-grain procedure is accompanied with an unitary transformation, called “disentangler”, which is designed to remove quantum entanglement at a given scale. In the MERA, a quantum ground state is thus described by a hierarchical structure that consists of coarse-graining and disentanglers acting at different scales. Ref. [6] proposed to relate the above iterative steps of the MERA to the extra dimension of the AdS.

(Alternatively, one can run the above procedure “backward” to develop an “IR-to-UV” picture; In this picture, we start from a uncorrelated IR state to describe the our target (ground) state at UV by using the coarse graining transformations iteratively. Along these steps, we use the “disentangler” to generate entanglements between spins, in such a way that the UV state correctly mimics the true ground state as closely as possible. See the main text for more details.)

An important hint for the connection between AdS/CFT and the MERA is obtained by comparing how the entanglement entropy is estimated in both cases [16]. (For reviews of the entanglement entropy in quantum many-body systems, see, e.g., [17, 18, 19, 20]). In the classical gravity limit of AdS/CFT, we can calculate the entanglement entropy S_A for a subregion A from the minimal area surface [21] (for reviews see [22]):

$$S_A = \frac{\text{Area}(\gamma_A)}{4G_N}, \quad (1)$$

where G_N is the Newton constant of the AdS gravity; γ_A is the minimal area surface which ends on the boundary of A at the AdS boundary. The holographic formula (1) has passed many tests: the analytical agreements in $\text{AdS}_3/\text{CFT}_2$ [21]; the strong subadditivity [23]; the phase transition when the subsystem A is disconnected [24]; the agreements of the coefficient of logarithmic terms [21, 25, 26]; moreover, the proof of (1) has been given in [26] when the subregion A is a round sphere. Strictly speaking, this prescription can be applied only to static systems. However, in general time-dependent backgrounds we can employ the covariant formulation in [27].

The holographic formula (1) already suggests a possibility of reconstructing the bulk spacetime in gravity from the quantum field theoretic data [27]. If we know the ground state of a given quantum field theory or quantum many body system, then we can in principle calculate the entanglement entropy S_A for any choice of subsystem A . Since S_A is related to the area of a minimal surface in its gravity dual (such as the AdS), it is natural to expect that we can reconstruct the metric of this gravitational spacetime by considering all possible choices of the subsystem A . Refer to [28, 29] for several developments in this direction.

The structure of the entanglement included in the (candidate) ground state in the MERA is set by its coarse-graining structure and the disentanglers. We can thus estimate the entanglement entropy S_A essentially by counting how many disentanglers, which may be operative at different iterative steps, are relevant for a given region A . Such counting gives us a bound for the entanglement entropy, which looks quite similar to the holographic formula (1) as pointed out in [6]. (See the main text for more details.)

Though traditionally the extra dimension of a AdS has often been identified with the energy scale of the Wilsonian renormalization group flow in momentum space [30, 31, 32], the calculation of the entanglement entropy suggests that AdS/CFT fits nicely with the real space renormalization group scheme, especially with the MERA. This is simply because the AdS metric is defined in the real space and it is not straightforward to see the structures in momentum space of its dual conformal field theories geometrically.

The purpose of this paper is to make the interpretation of AdS/CFT as the entanglement renormalization more concrete by looking closely at the holographic geometry of a given quantum

field theory. In order to match with AdS/CFT we need to take the continuum limit of the MERA. This is recently studied in [33] and is called the cMERA (continuous MERA). We will use this formalism and relate it to AdS/CFT. In particular, we propose a proper definition of metric in the extra dimension purely in terms of data of quantum field theories for translational invariant states. This will be a first step to understand an emergence of gravitational spacetime from quantum field theories based on the idea of holography. For earlier works on emergent gravity via holography refer to, e.g., [34, 7].

This paper is organized as follows: In section two, we introduce the idea of the MERA and cMERA. In section three, we formulate the cMERA for a free scalar field theory so that it includes a series of excited states. In section four, we study the connection between AdS/CFT and the (c)MERA; we introduce a holographic metric in the extra direction. In section five, we give analogous results for a free fermion theory in two dimension. In section six, we summarize our results discuss future problems.

2 Entanglement Renormalization: MERA and cMERA

In this section, we introduce and review the MERA (the multi-scale entanglement renormalization ansatz) [4], and its continuum counter part, the cMERA (the continuous multi-scale entanglement renormalization ansatz) [33]. They were proposed as an efficient (numerical) method to find a ground state of quantum many-body systems by the variational principle, and can be considered as an implementation of the real space renormalization group. Since the MERA can be thought of as an example of more general framework, called the tensor network algorithms or tensor network methods, let us start by describing tensor network algorithms in general, and in particular, one of their simplest examples; the matrix product states (MPS) and the density matrix renormalization group (DMRG).

2.1 Tensor Network Algorithms

A major challenge in quantum many-body problems is their exponentially-large Hilbert space. A successful (numerical) algorithm for quantum many-body systems should provide an efficient way to explore/access the physically relevant subspace of the total Hilbert space. (For example, Quantum Monte Carlo attempts to achieve this by importance sampling.) Different phases in the quantum many-body systems may be classified/categorized in terms of their computational complexity, or, equivalently, the scaling of the entanglement entropy as a function of the size of a spatial region of interest. The strategy of Tensor Network Algorithms (Tensor Network Methods) to attack quantum

many-body problems is to (i) target a given class of computational complexity and to (ii) find, within the given computational class, an optimal quantum state which most faithfully describes the true ground state. In this way, Tensor Network Methods avoid the exponential blow-up of the Hilbert space dimension as a function of the system size.

In the tensor network methods, a quantum state $|\Psi\rangle$ is described in terms of a set of tensors. Each tensor can be of arbitrary rank and can carry multiple indices. Some of the indices represent physical degrees of freedom (such as quantum spin degrees of freedom defined at each site of a give lattice system), while the others represent unphysical, auxiliary degrees of freedom that are introduced for the purpose of efficiently writing down a ground state – see below for more details. A physical wavefunction (quantum state) is represented as a product of tensors with properly contracted indices in the auxiliary spaces.

Tensor network representations of a quantum state can roughly be described in terms of their “structure” and “variational parameters”. The former includes the rank of tensors involved and how these tensors are contracted. This can often be described in terms of a network diagram, as in Figs. 1, 2, 3. This structural aspect largely sets the computational class of possible quantum states that the tensor network can describe. On the other hand, the latter includes the dimensions of auxiliary spaces and actual numerical values of tensor elements. They can be optimized, within a given structure of the tensor network, to find a best tensor network state which best describes the target quantum state.

The matrix product state (MPS) [35] or the density matrix renormalization group (DMRG) [36] is a canonical example of Tensor Network Algorithms in one spatial dimension, and one of the most successful algorithms for many-body quantum systems. Consider, as an example, a quantum spin chain with n $S = 1/2$ degrees of freedom. A quantum state $|\Psi\rangle$ is described by specifying the coefficients (wavefunction) $c(\sigma_1, \sigma_2, \dots, \sigma_n)$:

$$|\Psi\rangle = \sum_{\sigma_1, \sigma_2, \dots, \sigma_n} c(\sigma_1, \sigma_2, \dots, \sigma_n) |\sigma_1, \sigma_2, \dots, \sigma_n\rangle, \quad (2)$$

where $\sigma_i = 0, 1$ (spin up and down). In the MPS in one spatial dimension, we construct the coefficient $c(\sigma_1, \sigma_2, \dots, \sigma_n)$ as a product of tensors (tensor network) constructed from, as a building block, a tensor $M_{\alpha\beta}(\sigma)$ with three indices. Each tensor M can pictorially be represented as a “junction” or “tripod” as in the upper right part of Fig. 1. The tensor $M_{\alpha\beta}(\sigma)$ has one physical or spin index, and two auxiliary or “internal” indices α, β that take values $1, 2, \dots, J$; J is one of (variational) parameters of the tensor network. The coefficients $c(\sigma_1, \sigma_2, \dots, \sigma_n)$ in the MPS are given by considering n such “tripods”, which are, in simplest cases, all identical, and contracting indices for the auxiliary spaces for a given set of physical indices. Thus, $c(\sigma_1, \sigma_2, \dots, \sigma_n)$ in this

Figure 1: The matrix product state (MPS) for a quantum spin chain. The upper left diagram represents a tensor network for the MPS, which consists of “tripods” shown in the upper left diagram. The corresponding quantum state is shown below.

construction is given by a product of $J \times J$ matrices $M_{\alpha\beta}(\sigma)$ as

$$c(\sigma_1, \sigma_2, \dots, \sigma_n) = \text{Tr}[M(\sigma_1)M(\sigma_2) \cdots M(\sigma_n)]. \quad (3)$$

This is pictorially represented as in the upper left part of Fig. 1; When two legs of junctions ($= M$) are connected in the diagram, we contract the indices between them. In DMRG, a candidate for the ground state of the system is represented as a MPS, parameterized by a set of matrices $M_{\alpha\beta}(\sigma)$, and then it is variationally optimized. The candidate state can be systematically improved by increasing the dimension J of the auxiliary space.

By introducing higher rank tensors and considering tensors connected (contracted) via more complex network, the MPS can be extended to higher dimensions. Such an generalized framework is called projected entangled-pair states (PEPS) [37, 38].

Let us now ask, focusing again on systems in one spatial dimension, what kinds of quantum states can be represented as a MPS; what is the computational class of wavefunctions represented by the MPS? To answer this question, let us estimate the entanglement entropy S_A for MPS wavefunctions when bipartitioning the system into two subsystems A and B and taking a partial trace over B . One finds it is bounded as

$$S_A \leq 2 \log J. \quad (4)$$

This can be understood as follows. Upon bipartitioning, the only parts of the tensor network (MPS) that contribute to the entanglement entropy are the “bonds” which are “cut” by bipartitioning. These bonds are not a coupling in the physical Hamiltonian, but one of the legs of a tripod M which is connecting two auxiliary indices. The maximal contribution to the entanglement entropy from each bond is given by $\log J$. In this way we obtain the bound (4). The factor of two comes

Figure 2: The tensor network diagrams and the estimation of the entanglement entropy S_A for the matrix product state (MPS) (left) and for the tree tensor network (TTN) (right).

from the two ends of the region A . For later purposes, we introduce a curve γ_A to specify this partitioning; it has its ends on the interface of the subregions A and B , and it intersects with the two bonds in the tensor network; See the left panel in Fig. 2.

The entanglement entropy S_A can thus be made arbitrary large if we increase the dimension J of the auxiliary space. However, it does not scale with the size of the subregion A . On the other hand, it is well-known that the entanglement entropy in a one dimensional critical system (relativistic CFT) is proportional to $\log L$, where L is the size of the subsystem A [39, 40]. Therefore the bound (4) shows that MPS ansatz cannot realize the large amount of entanglement required to simulate quantum critical systems. (On the other hand, it is known that, the ground state of any one-dimensional gapped system can faithfully be represented by the MPS if J is sufficiently large.)

2.2 MERA

In order to look for an alternative to the MPS, which would work better for quantum critical systems, we need to modify the structure of the tensor network. The tensor network for the MERA is different from the MPS and has a layered structure as pictorially represented in Fig. 3. We label layers by an integer u according to their depth or generation. We take $u = 0, -1, -2, \dots, -\infty$ for later convenience. The original spin chain is located on the 0-th layer ($u = 0$), which is at the bottom of the tensor network in Fig. 3. The second layer ($u = -1$) is obtained by combining two spins into a single one by a linear map (isometry), which is regarded as a coarse graining procedure or equally the scale transformation; the layered structure is motivated by the real space renormalization group idea. We can repeatedly apply this procedure as many as one wishes. If the original system has n spins, there are $n \cdot 2^u$ spins on the layer u .

The coarse graining is, however, not the only ingredient of the MERA. In fact, if it were so, the tensor network would look like the right panel of Fig. 2; This tensor network construction is

called the tree tensor network (TTN). The entanglement entropy of the TTN is, again, bounded by a formula like (4), and does not scale as the function of the size of the subregion A . This can easily be understood pictorially from the right panel in Fig. 2. To remedy this situation, we are lead to add extra bonds called “disentangers”, as explained in Fig. 3. Physically, this means that we perform an appropriate unitary transformation on each of the Hilbert spaces of two spins. To summarize, the coarse graining procedure together with the disentangler defines the tensor network of the MERA [4]. The tensor network consists of tripods representing the coarse graining transformation (called “isometries”) and tetrapods which represent “disentangers”. As before, in order to obtain the ground state (numerically), we minimize the total energy by optimizing the parameters in isometries and disentangers. (See Fig. 3.)

In order to better understand the effects of disentangers, let us now estimate the entanglement entropy in the MERA for a subsystem A with L spins. For a general tensor network state, the entanglement entropy S_A is bounded as

$$S_A \leq \# \text{Bonds}(\gamma_A) \cdot \log J, \quad (5)$$

where $\# \text{Bonds}(\gamma_A)$ is the number of bonds intersected by γ_A in the tensor network. Notice that in general there are various choices for γ_A and $\# \text{Bonds}(\gamma_A)$ depends on the choice. Therefore we need to minimize this to obtain the most strict bound which can be saturated by the tensor network as

$$S_A \leq \text{Min}_{\gamma_A} [\# \text{Bonds}(\gamma_A)] \cdot \log J. \quad (6)$$

In the MERA for a spin chain, it is easy to estimate the curve γ_A which leads to the minimum entropy and we obtain the following bound as explained in Fig. 3:

$$S_A \leq c \cdot \log L, \quad (7)$$

where c is a numerical constant of order one. In this way, the entanglement structure of the MERA is consistent with that of quantum critical systems.

It is also worth while mentioning that it is straightforward to find higher dimensional versions of the MERA for e.g. spin systems in two and three spacial dimensions by changing the structure of the coarse-graining and the disentangers accordingly.

2.3 cMERA

For applications to quantum field theories, it is desirable to consider a continuum formulation of the MERA. One such formulation is recently explored in [33] and is called the cMERA (continuous MERA). This formulation is also useful in order to make clearer the connection between AdS/CFT and entanglement renormalization as we will explain in a later part of this paper.

Figure 3: (Left) The tensor network for the MERA and the estimation of the entanglement entropy. The brown trees describes the coarse-graining of the original spin chain. The red horizontal bonds describe the disentanglers, which is an unitary transformation acting on each pair of two spins. It is clear from this picture that we can estimate the entanglement entropy as $\text{Min}_{\gamma_A} [\# \text{Bonds}(\gamma_A)] \sim \log L$. (Right) The MERA tensor network consists of disentanglers (“tetrapods”) and isometries implementing coarse-graining (“tripod”).

Assume that a QFT with a Hamiltonian is given. We need to impose a UV cut off $\Lambda = \frac{1}{\epsilon}$, where ϵ can be identified as the lattice constant. We denote the Hilbert space defined by the fields with the UV cut off Λ as \mathcal{H}_Λ . As in the MERA [4, 5], we will perform coarse graining procedures. We thus consider a one-parameter family of wave functions (or states)

$$|\Psi(u)\rangle \in \mathcal{H}_\Lambda, \quad (8)$$

where u represents the length scale of interest. We take u such that the momentum k is effectively cut off as $|k| \leq \Lambda e^u$. We can regard u as the continuum analogue of u introduced in the MERA to specify the layers. It is important that we always work with the same microscopic Hilbert space \mathcal{H}_Λ . The UV limit and the IR limit are defined to be $u = u_{UV} = 0$ and $u = u_{IR} \rightarrow -\infty$.

We define the states in the IR and UV limit as follows:

$$|\Psi(u_{IR})\rangle \equiv |\Omega\rangle, \quad (9)$$

$$|\Psi(u_{UV})\rangle \equiv |\Psi\rangle. \quad (10)$$

The UV state $|\Psi\rangle$ is what describes the system we are studying, typically the ground state for a given Hamiltonian. In this paper we always assume that the system is described by a pure state. On the other hand, the IR state $|\Omega\rangle$ is a trivial state in that there is no quantum entanglement between any spacial regions in that system and the entanglement entropy vanishes $S_A = 0$ for any subsystem A defined in a real space. We can relate $|\Psi(u)\rangle$ and $|\Omega\rangle$ by a unitary transformation:

$$|\Psi(u)\rangle = U(u, u_{IR})|\Omega\rangle. \quad (11)$$

Equivalently we can represent $|\Psi(u)\rangle$ in terms of the UV state:

$$|\Psi\rangle = U(0, u)|\Psi(u)\rangle. \quad (12)$$

Now we express the unitary transformation as

$$U(u_1, u_2) = P \exp \left[-i \int_{u_2}^{u_1} (K(u) + L) du \right], \quad (13)$$

where $K(u)$ and L are the continuum analogue of the disentangler and the scale transformation (coarse graining) in the cMERA, respectively [33]. The symbol P means a path-ordering which puts all operators with smaller u to the right. For later convenience we also define \tilde{P} as the one with the opposite order.

We require that the IR state $|\Omega\rangle$ is invariant under the scale transformation L :

$$L|\Omega\rangle = 0. \quad (14)$$

This is because the IR state does not have any quantum entanglement and each spacial point behaves independently. On the other hand, following the discrete MERA, the operator $K(u)$ is designed to generate the entanglement for the modes with wave vectors $|k| \leq \Lambda e^u$, as becomes clearer from the later arguments. Therefore, (11) shows that the UV state $|\Psi\rangle$ is constructed from the non-entangled state $|\Omega\rangle$ by repeating the addition of the quantum entanglement and the scale transformation as u varies from $-\infty$ to 0. If we view this in an opposite way from the UV to IR limit, at each step we disentangle the system by $K(u)$ and then do a coarse-graining by L .

At first sight, the construction of quantum states by the cMERA looks quite different from the MERA. In particular, in the MERA the dimension of the Hilbert space (the number of spins) is reduced by half in each step of coarse graining, while in the cMERA the dimension of the Hilbert space is preserved. It is, however, possible to formulate the MERA in terms of a unitary evolution as in the cMERA. This can be done by simply adding a fixed dummy spin state $|0\rangle$ in each step of coarse graining in the MERA so that it keeps of the size of Hilbert space. The coarse-graining procedure in the cMERA can be more properly understood as the continuum limit of this latter definition of the MERA.

By moving to the 'Heisenberg picture', we can define an operator O at scale u as

$$O(u) = U(0, u)^{-1} \cdot O \cdot U(0, u), \quad (15)$$

where O is the operator in the UV limit. This satisfies

$$\langle \Psi | O | \Psi \rangle = \langle \Psi(u) | O(u) | \Psi(u) \rangle. \quad (16)$$

Finally it is useful to rewrite U in the ‘interaction picture’:

$$U(u_1, u_2) = e^{-iu_1 L} P e^{-i \int_{u_2}^{u_1} \hat{K}(u) du} \cdot e^{iu_2 L}, \quad (17)$$

where we defined

$$\hat{K}(u) = e^{iuL} \cdot K(u) \cdot e^{-iuL}. \quad (18)$$

In this way we find for the UV state:

$$|\Psi\rangle = P e^{-i \int_{u_{\text{IR}}}^0 \hat{K}(u) du} |\Omega\rangle. \quad (19)$$

In general, the operator $K(u)$ is chosen so that it creates the quantum entanglement for the scale below the UV cut off, i.e., $|k| \leq \Lambda$. The effective operator $\hat{K}(u)$ when we factor out the scale transformation is defined by (18) and thus $\hat{K}(u)$ generates the entanglement for the scale $|k| \leq \Lambda e^u$ in the expression (19) as advertised.

For a finite u , we get:

$$|\Psi(u)\rangle = e^{-iuL} \cdot P e^{-i \int_{u_{\text{IR}}}^u \hat{K}(s) ds} |\Omega\rangle. \quad (20)$$

For later purpose, it is also useful to define

$$|\Phi(u)\rangle = e^{iuL} |\Psi(u)\rangle = P e^{-i \int_{u_{\text{IR}}}^u \hat{K}(s) ds} |\Omega\rangle. \quad (21)$$

The physical meaning of the state $|\Phi(u)\rangle$ is as follows: as u varies from $-\infty$ to u , we add the entanglement by the operator $K(u)$. For the scale higher than u , we just perform the scale transformation L until it reaches the UV limit. This defines the state $|\Phi(u)\rangle$.

3 Analysis of cMERA in Free Scalar Field Theory

Here we analyze the cMERA in a free scalar field theory, which is the main example in this paper. We will closely follow the formulation in [33] (the appendix of version 1) and generalize this construction so that it can describe a class of excited states with a generic dispersion relation.

3.1 Formulation of cMERA in Free Scalar Field Theory

Consider the $(d+1)$ -dimensional free scalar field with the general dispersion relation ϵ_k . In momentum space, the Hamiltonian is given by

$$H = \frac{1}{2} \int d^d k [\pi(k) \pi(-k) + \epsilon_k^2 \cdot \phi(k) \phi(-k)]. \quad (22)$$

The results for a standard massive relativistic scalar field is obtained by setting $\epsilon_k = \sqrt{k^2 + m^2}$.

We can express $\phi(k)$ and $\pi(k)$ in terms of creation and annihilation operators

$$\phi(k) = \frac{a_k + a_{-k}^\dagger}{\sqrt{2\epsilon_k}}, \quad \pi(k) = \sqrt{2\epsilon_k} \left(\frac{a_k - a_{-k}^\dagger}{2i} \right). \quad (23)$$

The commutation relation between a_k and a_k^\dagger is given by

$$[a_k, a_p^\dagger] = \delta^d(k - p), \quad (24)$$

which is equivalent to

$$[\phi(k), \pi(p)] = i\delta^d(k + p). \quad (25)$$

First, we define the IR state $|\Omega\rangle$ by

$$\left(\sqrt{M}\phi(x) + \frac{i}{\sqrt{M}}\pi(x) \right) |\Omega\rangle = 0, \quad (26)$$

where M is a constant, which is taken to be order of the UV cut off Λ as we will confirm later. Note that for this state $|\Omega\rangle$, the entanglement entropy S_A is indeed vanishing for any subsystem A because all modes for any x are decoupled from each other. It satisfies

$$\langle\Omega|\phi(k)\phi(k')|\Omega\rangle = \frac{1}{2M}\delta^d(k + k'), \quad \langle\Omega|\pi(k)\pi(k')|\Omega\rangle = \frac{M}{2}\delta^d(k + k'). \quad (27)$$

In the oscillator expression, $|\Omega\rangle$ is defined by the property

$$(\alpha_k a_k + \beta_k a_{-k}^\dagger) |\Omega\rangle = 0, \quad (28)$$

where

$$\alpha_k = \frac{1}{2} \left(\sqrt{\frac{M}{\epsilon_k}} + \sqrt{\frac{\epsilon_k}{M}} \right), \quad \beta_k = \frac{1}{2} \left(\sqrt{\frac{M}{\epsilon_k}} - \sqrt{\frac{\epsilon_k}{M}} \right). \quad (29)$$

The IR state $|\Omega\rangle$ is invariant under the (non-relativistic) scale transformation L :

$$\begin{aligned} e^{-iuL}\phi(x)e^{iuL} &= e^{\frac{d}{2}u}\phi(e^u x), & e^{-iuL}\phi(k)e^{iuL} &= e^{-\frac{d}{2}u}\phi(e^{-u}k), \\ e^{-iuL}\pi(x)e^{iuL} &= e^{\frac{d}{2}u}\pi(e^u x), & e^{-iuL}\pi(k)e^{iuL} &= e^{-\frac{d}{2}u}\pi(e^{-u}k). \end{aligned} \quad (30)$$

Note that L differs from the standard (relativistic) scale transformation L' which is given by

$$\begin{aligned} e^{-iuL'}\phi(x)e^{iuL'} &= e^{\frac{d-1}{2}u}\phi(e^u x), & e^{-iuL'}\phi(k)e^{iuL'} &= e^{-\frac{d+1}{2}u}\phi(e^{-u}k), \\ e^{-iuL'}\pi(x)e^{iuL'} &= e^{\frac{d+1}{2}u}\pi(e^u x), & e^{-iuL'}\pi(k)e^{iuL'} &= e^{-\frac{d-1}{2}u}\pi(e^{-u}k). \end{aligned} \quad (31)$$

Now, we introduce the disentangler as follows [33]

$$K(u) = \frac{1}{2} \int d^d k [g(k, u)(\phi(k)\pi(-k) + \pi(k)\phi(-k))]. \quad (32)$$

We assume⁴ that the k dependence of the real valued function $g(k, u)$ is s-wave i.e. only depends on $|k|$. The function $g(k, u)$ is assumed to have the following form

$$g(k, u) = \chi(u) \cdot \Gamma(|k|/\Lambda), \quad (33)$$

where $\Gamma(x) = \theta(1 - |x|)$ is the cut off function ($\theta(x)$ is the step function); $\chi(u)$ is a real valued function. Although at this point (32) is an ansatz to find a ground state, we will show later that it produces the exact ground state. Then the transformation $U(0, u)$ defined by (13) acts as

$$\begin{aligned} U(0, u)^{-1} \phi(k) U(0, u) &= e^{-f(k, u)} e^{-\frac{u}{2} d} \phi(e^{-u} k), \\ U(0, u)^{-1} \pi(k) U(0, u) &= e^{f(k, u)} e^{-\frac{u}{2} d} \pi(e^{-u} k). \end{aligned} \quad (34)$$

Notice that in the interaction picture (19) we find

$$\begin{aligned} \hat{K}(u) &= \frac{1}{2} \int d^d k e^{du} [g(k, u) \phi(k e^u) \pi(-k e^u) + g(k, u) \pi(k e^u) \phi(-k e^u)] \\ &= \frac{1}{2} \int d^d k [g(k e^{-u}, u) \phi(k) \pi(-k) + g(k e^{-u}, u) \pi(k) \phi(-k)]. \end{aligned} \quad (35)$$

The function $f(k, u)$ satisfies

$$\frac{\partial f(k, u)}{\partial u} = g(k e^{-u}, u), \quad (36)$$

which is solved as

$$f(k, u) = \int_0^u ds g(k e^{-s}, s). \quad (37)$$

Note that the final expression in (35) shows that the momentum integral in $\hat{K}(u)$ has the cut off $|k| \leq \Lambda e^s$.

Finally we apply the variational principle and minimize the energy [33]. The total energy E is given by

$$\begin{aligned} E &= \langle \Psi | H | \Psi \rangle = \langle \Omega | H(u_{\text{IR}}) | \Omega \rangle \\ &= \langle \Omega | \int d^d k \frac{1}{2} \left[e^{2f(k, u_{\text{IR}})} e^{-u_{\text{IR}} d} \pi(k e^{-u_{\text{IR}}}) \pi(-k e^{-u_{\text{IR}}}) \right. \\ &\quad \left. + \epsilon_k^2 \cdot e^{-2f(k, u_{\text{IR}})} e^{-u_{\text{IR}} d} \phi(k e^{-u_{\text{IR}}}) \phi(-k e^{-u_{\text{IR}}}) \right] | \Omega \rangle \\ &= \int d^d x \int d^d k \frac{1}{4} \left[e^{2f(k, u_{\text{IR}})} M + \frac{\epsilon_k^2}{M} e^{-2f(k, u_{\text{IR}})} \right]. \end{aligned} \quad (38)$$

⁴More generally we can consider a disentangler which is not s-wave, where $g(k, u)$ depends not only $|k|$ but also on the vector k as $g(k, u) = a_{i_1 i_2 \dots i_l}(|k|, u) \cdot k^{i_1} k^{i_2} \dots k^{i_l}$. The free fermion theory corresponds to $l = 1$ example in this sense as we will seen in section 5. In the light of holography, such a generalization will correspond to the excitations of higher spin fields in the dual higher spin gravity theory as we will comment in the final section.

We require the variation of E with respect to $\chi(u)$ for any u is vanishing:

$$\frac{\delta E}{\delta \chi(u)} = \int d^d x \int d^d k \left(e^{2f(k, u_{\text{IR}})} M - \frac{\epsilon_k^2}{M} e^{-2f(k, u_{\text{IR}})} \right) \Gamma(|k|e^{-u}/\Lambda) = 0. \quad (39)$$

Thus we find

$$f(k, u_{\text{IR}}) = \frac{1}{2} \log \frac{\epsilon_k}{M}, \quad (|k| < \Lambda). \quad (40)$$

By using

$$f(k, u_{\text{IR}}) = \int_0^{u_{\text{IR}}} g(ke^{-s}, s) ds = \int_0^{-\log \Lambda/|k|} \chi(s) ds, \quad (41)$$

we obtain

$$\chi(u) = \frac{1}{2} \cdot \left(\frac{|k| \partial_{|k|} \epsilon_k}{\epsilon_k} \right) \Big|_{|k|=\Lambda e^u}. \quad (42)$$

This characterizes the ground state $|\Phi\rangle$ of the free scalar field theory given by the Hamiltonian (22).

In particular, for the free scalar field theory with a mass m [33] we obtain

$$\chi(u) = \frac{1}{2} \cdot \frac{e^{2u}}{e^{2u} + m^2/\Lambda^2}, \quad M = \sqrt{\Lambda^2 + m^2}. \quad (43)$$

The function $f(k, u)$ is given by

$$f(k, u) = \begin{cases} \frac{1}{4} \log \frac{m^2 + e^{2u} \Lambda^2}{m^2 + \Lambda^2}, & (|k| < \Lambda e^u) \\ \frac{1}{4} \log \frac{k^2 + m^2}{m^2 + \Lambda^2}. & (|k| > \Lambda e^u) \end{cases}$$

Some comments are in order here. In the CFT (massless limit), we always have $\chi(u) = \frac{1}{2}$. Thus one can show that the total operation $K + L$ at each scale coincides with the relativistic scale transformation (dilatation) L' of the CFT. In the massive case, we have $\chi(u) \simeq \frac{1}{2}$ in the UV region, i.e., $e^u \gg \frac{m}{\Lambda}$. On the other hand, in the IR region $e^u \ll \frac{m}{\Lambda}$, we have $\chi(u) \simeq 0$ and the unitary transformation acts trivially, corresponding to the absence of mass gap.

It is also intriguing to consider non-standard scalar fields. If we assume the dispersion relation $\epsilon_k \propto k^\nu$, which corresponds to a Lifshitz theory (anisotropic scale invariant theory) with the dynamical exponent ν , we again find that $\chi(u)$ takes a constant value

$$\chi(u) = \frac{\nu}{2}. \quad (44)$$

3.2 Excited States in cMERA

Here we would like to describe a class of excited states in the cMERA given by the coherent states:

$$(A_k a_k + B_k a_{-k}^\dagger) |\Psi_{ex}\rangle = 0, \quad (45)$$

where we normalize

$$|A_k|^2 - |B_k|^2 = 1. \quad (46)$$

Notice that the definition of (A_k, B_k) still has the ambiguity of phase factor. The ground state corresponds to the choice $B_k = 0$.

We want to relate the UV state $|\Psi_{ex}\rangle$ to the unentangled IR state $|\Omega\rangle$ via the unitary transformation

$$|\Psi_{ex}\rangle = P e^{-i \int_{u_{\text{IR}}}^0 \hat{K}_\psi(u) du} |\Omega\rangle, \quad (47)$$

as in (19). In terms of oscillators, we assume the form

$$\hat{K}_\psi(u) = \frac{i}{2} \int d^d k \left(g_k(u) a_k^\dagger a_{-k}^\dagger - g_k^*(u) a_k a_{-k} \right), \quad (48)$$

where the function g_k is taken to be the form

$$g_k(u) = g(u) \Gamma(|k| e^{-u}/\Lambda). \quad (49)$$

For example, $\hat{K}(u)$ in (35) can be written in this form with the identification $g_k(u) = \Gamma(|k| e^{-u}/\Lambda) \chi(u)$.

In general $g_k(u)$ takes complex values and $\hat{K}_\psi(u)$ cannot be cast into the form (35).

To proceed, it is useful to look at how the unitary transformation in (47) acts on the creation and annihilation operators. It is given by a linear transformation of the following form:

$$P e^{-i \int_{u_{\text{IR}}}^u \hat{K}_\psi(u) du} \cdot \begin{pmatrix} a_k \\ a_{-k}^\dagger \end{pmatrix} \cdot \tilde{P} e^{i \int_{u_{\text{IR}}}^u \hat{K}_\psi(u) du} = \begin{pmatrix} p_k(u) & q_k(u) \\ q_k^*(u) & p_k^*(u) \end{pmatrix} \cdot \begin{pmatrix} a_k \\ a_{-k}^\dagger \end{pmatrix}. \quad (50)$$

Here $p_k(u)$ and $q_k(u)$ are given in terms of $g_k(u)$ in the following way:

$$M_k(u) \equiv \begin{pmatrix} p_k(u) & q_k(u) \\ q_k^*(u) & p_k^*(u) \end{pmatrix} = \tilde{P} \exp \left(- \int_{u_{\text{IR}}}^u du G_k(u) \right), \quad (51)$$

where the matrix $G_k(u)$ is defined by

$$G_k(u) = \begin{pmatrix} 0 & g_k(u) \\ g_k^*(u) & 0 \end{pmatrix} = \Gamma(|k| e^{-u}/\Lambda) \begin{pmatrix} 0 & g(u) \\ g^*(u) & 0 \end{pmatrix}. \quad (52)$$

The matrix $M_k(u)$ defined by (51) satisfies

$$\frac{dM_k(u)}{du} = -M_k(u) G_k(u). \quad (53)$$

$M_k(u)$ clearly satisfies $|p_k(u)|^2 - |q_k(u)|^2 = 1$ and preserves the commutation relations between a_k and a_k^\dagger .

Eventually, for the UV state $|\Psi_{ex}\rangle$, we find that (A_k, B_k) in the definition (45) is related to the IR values (α_k, β_k) by

$$(A_k, B_k) = (\alpha_k, \beta_k) \cdot M_k(0). \quad (54)$$

As is clear from (52) in general we can decompose $G_k(s)$ into two pieces

$$G_k(u) = \tilde{G}(u)\Gamma(|k|e^{-u}/\Lambda). \quad (55)$$

This allows us to rewrite $M_k(0)$

$$M_k(0) = \tilde{P} \cdot \exp \left(- \int_{\log \frac{|k|}{\Lambda}}^0 du \tilde{G}(u) \right). \quad (56)$$

Notice the relation

$$\tilde{G}_{11}(u) = \tilde{G}_{22}^*(u) = -\tilde{G}_{11}^*(u), \quad \tilde{G}_{12}(u) = \tilde{G}_{21}^*(u). \quad (57)$$

It is also useful to extend the previous construction to the state at scale u

$$|\Psi_{ex}(u)\rangle = e^{-iuL} \cdot P e^{-i \int_{u_{\text{IR}}}^u \hat{K}_\psi(s) ds} |\Omega\rangle = e^{-iuL} |\Phi_{ex}(u)\rangle, \quad (58)$$

as we did in (20). Since $|\Psi_{ex}(u)\rangle$ is obtained from the scale transformation of $|\Phi_{ex}(u)\rangle$, we need only to consider the relation between $|\Phi_{ex}(u)\rangle$ and $|\Omega\rangle$. This can be found from (50) as follows:

$$(A_k(u), B_k(u)) = (\alpha_k, \beta_k) \cdot M_k(u), \quad (59)$$

where we assumed that $|\Phi_{ex}(u)\rangle$ satisfies $(A_k(u)a_k + B_k(u)a_{-k}^\dagger)|\Phi_{ex}(u)\rangle = 0$.

Before we go on we have a few remarks. Notice that $M_k(u)$ satisfies

$$M_k(u)^\dagger \sigma_3 M_k(u) = \sigma_3, \quad \det M_k(u) = 1, \quad (60)$$

which says that $M_k(u)$ belongs to $SU(1, 1)$.

The parametrization (52) covers only two out of three generators of $SU(1, 1)$. The remaining one is found to be the form

$$e^{i\delta_k(u)\sigma_3} \in SU(1, 1). \quad (61)$$

If we fix (α_k, β_k) and ask if we can find $M_k(u)$ for an arbitrarily given pair (A_k, B_k) , $M_k(u)$ should have three parameters. However, if we remember that (A_k, B_k) is defined up to a phase factor, $M_k(u)$ only needs to have two parameters. Therefore, the ansatz (52) is enough and we can ignore the one (61).

3.2.1 Ground State

The ground state of the cMERA corresponds to $A_k = 1$ and $B_k = 0$ and thus we find from (59)

$$M_k(0) = \begin{pmatrix} \alpha_k & -\beta_k \\ -\beta_k & \alpha_k \end{pmatrix}. \quad (62)$$

If we assume that $g_k(u)$ takes only real values i.e. $g_k = (g_k)^*$, then we find from (52)

$$M_k(u) = \begin{pmatrix} \cosh \int_{u_{\text{IR}}}^u du g_k(u) & -\sinh \int_{u_{\text{IR}}}^u du g_k(u) \\ -\sinh \int_{u_{\text{IR}}}^u du g_k(u) & \cosh \int_{u_{\text{IR}}}^u du g_k(u) \end{pmatrix}. \quad (63)$$

By comparing between these in the UV limit $u = 0$, we need to require

$$e^{\int_{u_{\text{IR}}}^0 du g_k(u)} = \sqrt{\frac{M}{\epsilon_k}}. \quad (64)$$

This is equivalent to (40) and therefore indeed it agrees with the result in the previous section. The explicit form of g_k is given by

$$g_k(u) = \chi(u) \Gamma(|k|e^{-u}/\Lambda), \quad (65)$$

where $\chi(u)$ is defined in (42). In this example of the ground state, the matrix $G_k(s)$ (52) explicitly reads

$$G_k(s) = \chi(u) \Gamma(|k|e^{-u}/\Lambda) \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}. \quad (66)$$

3.3 Time-dependent Excited State

We can find $p_k(0)$ and $q_k(0)$ (or equivalently $M_k(0)$) from A_k and B_k as follows:

$$\begin{aligned} p_k(0) &= \alpha_k A_k - \beta_k B_k^*, \\ q_k(0) &= -\beta_k A_k^* + \alpha_k B_k. \end{aligned} \quad (67)$$

By taking the derivative with respect to the momentum k , we obtain from (56)

$$\begin{aligned} \tilde{G} \left(\log \frac{|k|}{\Lambda} \right) &= |k| \frac{dM(0)}{d|k|} \cdot M^{-1}(0) \\ &= \begin{pmatrix} |k|(\partial_{|k|} p) p^* - |k|(\partial_{|k|} q) q^* & |k|p(\partial_{|k|} q) - |k|q(\partial_{|k|} p) \\ -|k|(\partial_{|k|} p^*) q^* + |k|p^*(\partial_{|k|} q^*) & -|k|q(\partial_{|k|} q^*) + |k|p(\partial_{|k|} p^*) \end{pmatrix}, \end{aligned} \quad (68)$$

where we omit, for simplicity, the arguments of $p_k(0)$ and $q_k(0)$ as p and q . After we calculate $\tilde{G}(u)$ from (68), we can eventually compute $M_k(s)$ following (51) in principle.

We would like to analyze a class of excited states given by (45). In particular, we assume that at time $t = 0$, the ratio A_k/B_k is real. This includes the important examples of quantum quenches discussed later. By taking into its time evolution, A_k and B_k are given by the following form:

$$\begin{aligned} A_k &= \sqrt{1 + a_k^2} \cdot e^{i\epsilon_k t + i\theta_k}, \\ B_k &= a_k \cdot e^{-i\epsilon_k t + i\theta_k}, \end{aligned} \quad (69)$$

where a_k is taken to be an arbitrary real valued function of k . The phase θ_k is a redundant parameter on which the UV state $|\Psi_{ex}\rangle$ does not depend. We choose θ_k such that $\tilde{G}_{11} = 0$. Considering the limit $M \sim \Lambda \gg \epsilon_k$, we obtain

$$\partial_{|k|}\theta_k = t \left(2a_k \sqrt{1 + a_k^2} \cos 2\theta_k - 1 - 2a_k^2 \right) \partial_{|k|}\epsilon_k - \frac{\partial_{|k|}a_k \cdot \sin 2\theta_k}{\sqrt{1 + a_k^2}}, \quad (70)$$

$$\tilde{G}_{12} = g \left(\log \frac{|k|}{\Lambda} \right) = \frac{|k| \partial_{|k|}\epsilon_k}{2\epsilon_k} \left(1 + 4ta_k \epsilon_k \sqrt{1 + a_k^2} \sin 2\theta_k \right) + \frac{|k| \partial_{|k|}a_k \cdot \cos 2\theta_k}{\sqrt{1 + a_k^2}}. \quad (71)$$

Note that this shows that the function $g(u)$ in this final expression (71) is real valued in the low energy region $-u \gg 1$. This property is no longer true in the high energy region $u \sim 0$, where similar calculations lead to a slightly complicated expression. Below we focus on the former region as that is enough to find the essential property we want. Since $g(u)$ is real, we can find the expression of $M_k(s)$ and it is given by (63) with $\chi(u)$ replaced with $g(u)$.

One important property which we can find from (71) is that at late time $g(u)$ increases linearly in general as long as $a_k \neq 0$. This agrees with the fact that the entanglement entropy generally grows linearly under a time evolution after a strong excitation (or called quantum quench) [41] as we explain in the next section.

One may notice that the choice of θ_k has an ambiguity which corresponds to an integration constant when we solve (70). In other words, \tilde{G}_{12} or equally $g(u)$ depend on the choice of θ_k . This is because even though the UV state $|\Psi_{ex}\rangle$ defined in (45) is independent from the choice of θ_k , the middle energy state $|\Psi_{ex}(u)\rangle$ (or equally $|\Phi_{ex}(u)\rangle$) does depend on θ_k . There does not seem to exist any uniquely preferable choice of θ_k . This means that the definition of the cMERA for a given excited state is not unique at least within the current approach. We will later discuss the holographic interpretation of this ambiguity and argue that it corresponds to the choice of time slices extended into the extra dimension.

3.4 Global Quantum Quenches

One convenient physical process to create an strongly excited state is the global quantum quench where the system uniformly gets excited by a sudden shift of some parameters such as mass or

Figure 4: The time-evolution of $\tilde{G}_{12} = g(u)$ after a quantum quench, computed for $m = 0.1$ and $m_0 = 1$ using the same approximation in (73). We fixed the phase ambiguity as $\theta_0(t) = 0$. The horizontal and vertical coordinate correspond to $1/|k| = \epsilon e^{-u}$ and t , respectively. The former, $1/|k|$, can be interpreted as the z coordinate in the AdS as we explain in section 4. With this interpretation, we can observe, qualitatively, that the excitations induced by the quantum quench are within the light-cone: $z < t$ in the AdS.

coupling constants [41, 18]. Here we consider the global quench triggered by the shift of mass of the free scalar. Especially, we choose it such that the mass is m_0 for $t < 0$ and it suddenly goes to m at $t = 0$ and later.

By requiring that the field and its momentum are continuous at $t = 0$, we find the system for $t > 0$ coincides with the excited state (45) defined by (71) with the specific choice of a_k

$$a_k = \frac{1}{2} \left[\left(\frac{k^2 + m_0^2}{k^2 + m^2} \right)^{\frac{1}{4}} - \left(\frac{k^2 + m^2}{k^2 + m_0^2} \right)^{\frac{1}{4}} \right]. \quad (72)$$

Let us consider the case where $m = 0$ i.e. $\epsilon_k = |k|$ so that we obtain a CFT after the quench. The differential equations (70) and (71) get simpler in the region $m_0 \ll |k| \ll \Lambda$ and we can solve as

$$\begin{aligned} \theta_k &\simeq -|k|t + \theta_0(t), \\ \tilde{G}_{12} = g\left(\log \frac{|k|}{\Lambda}\right) &\simeq \frac{1}{2} - \frac{m_0^2}{2|k|} t \sin(2|k|t - \theta_0(t)) - \frac{m_0^2}{2k^2} \cos(2|k|t - \theta_0(t)), \end{aligned} \quad (73)$$

where $\theta_0(t)$ is an undetermined integration constant as discussed in the previous subsection. We plotted the form of $\tilde{G}_{12} = g(u)$ as a function of $1/|k|$ and t by choosing $\theta_0(t) = 0$ in Fig. 4, where introduced the IR cut off by turning on m slightly so that the divergence of a_k (72) in the IR limit $|k| \rightarrow 0$ is regularized.

4 AdS/CFT and Entanglement Renormalization

As we have explained, the MERA and the cMERA are a useful tool in quantum many-body problems and quantum field theories, and can be viewed as an efficient implementation of the real space renormalization group idea. As conjectured in [6] (see also [42, 33] for later related arguments), it is natural to expect some relation between the MERA/cMERA and the AdS/CFT correspondence, where in the latter the extra direction in a AdS is interpreted as the energy scale of the renormalization group flow. The purpose of this section is to materialize this interpretation by introducing a proper metric structure for the tensor networks in the MERA/cMERA.

4.1 MERA and AdS/CFT Correspondence

The holographic formula (1) provides us with a way to compute the entanglement entropy in a QFT from the bulk geometry. Since AdS/CFT is a duality, it would be possible to “read backward” the holographic dictionary, and infer the bulk geometry from entanglement in the QFT. This strategy could be extended to a generic class of QFTs, and in particular to QFTs for which we can find a ground state by the MERA. Therefore, let us start by remembering how the entanglement entropy can be estimated for a wavefunction represented in terms of a MERA network; it was discussed in Sec. 2.2. The entanglement entropy in the MERA network is bounded as (7) (and (6) for the case of one-dimensional critical systems). In particular, if each bond is maximally entangled the equality in (7) should hold. This bound shows that the entanglement entropy can be estimated by the minimum of the number of bonds cut among choices of divisions γ_A for a given tensor network (see the left picture in Fig. 5). This estimation of the entanglement entropy in MERA is very analogous to that of the holographic entanglement entropy [6].

This identification between the surface γ_A in the MERA and γ_A in the holographic formula suggests the relation

$$\#\text{Bonds} \simeq \frac{\text{Area}(\gamma_A)}{G_N}, \quad (74)$$

assuming that the bonds are maximally entangled. Note that the minimization of both sides agree with each other consistently. Here \simeq means the equality up to a numerical factor of order one. This relation (74) suggests, at least, a strong correlation between the entanglement in a QFT and the bulk geometry (if it exists). The relation (74) can also be thought of as a natural generalization of the standard microscopic interpretation of black hole entropy, in that it says that the area of a minimal surface (measured in the unit of Planck length) corresponds to the number of entangling bonds.

The comparison between the holographic formula and the entanglement entropy bound in the

Figure 5: The parallelism between the calculations of the entanglement entropy S_A in the MERA (left) and AdS/CFT (right). The green surface represents γ_A in both pictures. The red bonds in the left denote the disentanglers.

MERA further suggests the extra direction in the AdS is identified with the u in the MERA which counts the layers of each coarse-grained spin system (Fig. 5). To be more precise, let us write the $(d+2)$ -dimensional AdS metric in the form

$$ds_{\text{AdS}}^2 = du^2 + \frac{e^{2u}}{\epsilon^2} (d\vec{x}^2 - dt^2) = \frac{dz^2 - dt^2 + d\vec{x}^2}{z^2}, \quad (75)$$

where \vec{x} describes the coordinate of R^d ; ϵ is the lattice spacing of the spin system. We normalize the radius of the AdS to be unity for simplicity; $z = \epsilon \cdot e^{-u}$ is the standard radial coordinate of Poincare AdS. The extra direction u in the AdS is identified with u in the MERA when it is representing a ground state of a conformal invariant system (they are equal up to a proportionality constant as we explain below).

In the above example of a conformal invariant system, the component of the metric g_{uu} is constant. This is in line with the fact that in the scale invariant the MERA, the structure of the tensor network, including the disentanglers, do not change as we go deeper into the IR region (by increasing the layer index u). For quantum field theories which are not conformally invariant, the MERA network would evolve in a more complex way. To describe such situations, we denote, by $n(u)$, the typical strength of the bonds (or the number of bonds) at the layer specified by the non-positive integer u . For the MERA for CFTs, $n(u)$ does not depend on u . The MERAs for non-CFTs are expected to correspond to the gravity dual with the metric

$$ds^2 = g_{uu} du^2 + \frac{e^{2u}}{\epsilon^2} d\vec{x}^2 + g_{tt} dt^2. \quad (76)$$

The metric for \vec{x} is fixed because we employ the same coarse-graining procedure. The metric g_{uu} in the extra dimension is related to the density of disentanglers, i.e., $n(u)$ as we explain soon later.

The temporal component of the metric g_{tt} cannot be determined from the information of entanglement entropy S_A . If we generalize the definition of the entanglement entropy so that the

subsystem A is defined on a Lorentz boosted time slice, in principle, we can read off g_{tt} , although we will not discuss this issue in detail in this paper.

To relate the MERA to the geometry (76), let us calculate the entanglement entropy S_A when A is the half of the space (i.e., we consider the equal bipartition of the total space). The calculation in the MERA when the system is a one-dimensional spin chain is depicted in Fig. 6. In the MERA for a $(d+1)$ -dimensional quantum system, following the previous discussion, we can estimate the entanglement entropy as

$$S_A \propto L^{d-1} \sum_{u=-\infty}^0 n(u) \cdot 2^{(d-1)u}, \quad (77)$$

where L^{d-1} is the number of lattice points on the boundary of A . On the other hand, the holographic formula in AdS/CFT (1) leads to

$$S_A = \frac{1}{4G_N} \cdot \frac{V_{d-1}}{\epsilon^{d-1}} \int_{u_{\text{IR}}(=-\infty)}^{u_{\text{UV}}(=0)} du \sqrt{g_{uu}} e^{(d-1)u}, \quad (78)$$

where V_{d-1} is the area of the boundary of A . In the continuum limit $\epsilon \rightarrow 0$, using the obvious relation $V_{d-1} = L^{d-1} \epsilon^{d-1}$, we find that (77) and (78) have the similar structure; The comparison between the two calculations suggest that the layer index u in the MERA and the radial coordinate u AdS/CFT are related as $u_{\text{AdS/CFT}} = \log 2 \cdot u_{\text{MERA}}$, and moreover,

$$n(u) \propto \frac{\sqrt{g_{uu}}}{G_N}. \quad (79)$$

This implies that we can interpret the MERA in the general setups as the holography.

The arguments so far are based on the MERA for discrete quantum systems. In order to make the connection to AdS/CFT more precise, it would be desirable to take the continuum limit from the beginning by employing the idea of the cMERA [33] and this will be the main purpose in coming subsections. Especially we would like to give an interpretation of the cMERA in terms of holography by defining an appropriate metric g_{uu} from the cMERA for any given quantum field theory. Before we go on to the construction of metric in the cMERA, we would like to introduce a natural metric in quantum mechanics.

We close this subsection with one important comment. In AdS/CFT, we need to take the large N and strong coupling limit of gauge theories in order to realize the classical gravity limit (or equally Einstein gravity limit) where the holographic formula (1) can be applied. If we abandon the strong coupling limit, we expect higher derivative corrections to the Einstein gravity and the holographic entanglement entropy also includes higher derivative terms [43, 44]. If we do not take the large N limit, the gravity theory receives substantial quantum gravity corrections and the effective gravity action will become highly non-local, for which the holographic entanglement entropy has not been

Figure 6: The calculation of the entanglement entropy S_A in the MERA for a one dimensional system, when the subsystem A is the half of the total space.

calculated at present. Therefore, one may wonder how these two limits can be seen in the MERA. Though we are not going to address a definite answer to this question, we can suggest a related important idea. In order to justify the identification (74), we need to assume that the all relevant bonds are (almost) maximally entangled. If this is not the case, the precise estimation of the entanglement entropy gets quite complicated, and we need the information of entanglement of bonds which is far from the minimal surface γ_A . Therefore, in such situations, calculations are expected to be “non-local” in the sense of tensor network geometry, which is identified with a AdS space. This may correspond to the fact that the bulk gravity becomes non-local if we do not take the large N limit. At the same time, it is natural to expect that the description in terms of maximally entangled bonds can be valid in this limit. We would like to leave more understandings for an important future problem⁵.

4.2 Quantum Distance

Suppose we are given two quantum states in the Hilbert space. They can be pure or mixed states. For our discussion below, we only need pure states. However, let us be general for a moment, and consider two mixed states, characterized by a density matrix ρ_1 and ρ_2 , respectively. To measure how different these states are, we can introduce a proper distance. The Bures distance is given by

$$D_B(\rho_1, \rho_2) := 2 \left(1 - \text{Tr} \sqrt{\rho_1^{1/2} \rho_2 \rho_1^{1/2}} \right). \quad (80)$$

Alternatively, one can consider the Hilbert-Schmidt distance defined by

$$D_{\text{HS}}(\rho_1, \rho_2) := \frac{1}{2} \text{Tr} (\rho_1 - \rho_2)^2. \quad (81)$$

⁵ After the preprint of this paper appeared on the arXiv, we noticed the preprint [45], where interesting behaviors in the large N limit of MERA were discussed.

When ρ_1 and ρ_2 are pure, and given by $\rho_1 = |\psi_1\rangle\langle\psi_1|$ and $\rho_2 = |\psi_2\rangle\langle\psi_2|$, respectively, these definitions reduce to

$$\begin{aligned} D_B(\rho_1, \rho_2) &= D_B(\psi_1, \psi_2) = 2(1 - |\langle\psi_1|\psi_2\rangle|), \\ D_{HS}(\rho_1, \rho_2) &= D_{HS}(\psi_1, \psi_2) = 1 - |\langle\psi_1|\psi_2\rangle|^2. \end{aligned} \quad (82)$$

Similarly, for a set of quantum states $\{\rho(\xi)\}$ parameterized by finite numbers of real parameters $\xi = (\xi_1, \xi_2, \dots)$, we can define the distance between them by $D_B[\rho(\xi), \rho(\xi + d\xi)]$ or $D_{HS}[\rho(\xi), \rho(\xi + d\xi)]$. Assuming the quantum state $\rho(\xi)$ changes smoothly as a function of ξ , we can expand $D_{B/HS}[\rho(\xi), \rho(\xi + d\xi)]$ for infinitesimal $d\xi$. Specializing to the case of pure states, $\rho(\xi) = |\psi(\xi)\rangle\langle\psi(\xi)|$,

$$D_B[\psi(\xi), \psi(\xi + d\xi)] = D_{HS}[\psi(\xi), \psi(\xi + d\xi)] = g_{ij}(\xi) d\xi_i d\xi_j, \quad (83)$$

where we have introduced the quantum metric tensor (or equally Fisher information metric) by

$$g_{ij}(\xi) = \text{Re} \langle \partial_i \psi(\xi) | \partial_j \psi(\xi) \rangle - \langle \partial_i \psi(\xi) | \psi \rangle \langle \psi | \partial_j \psi(\xi) \rangle. \quad (84)$$

$g_{ij}(\xi)$ transforms in a covariant fashion under reparameterization, $\xi \rightarrow \xi'(\xi)$, $g_{ij}(\xi) = (\partial \xi'_k / \partial \xi_i) (\partial \xi'_l / \partial \xi_j) g_{kl}(\xi')$.

As an example, let us consider a system with two bosonic oscillators defined by creation and annihilation operators (a, b) and (a^\dagger, b^\dagger) . They satisfy the commutation relations $[a, a^\dagger] = [b, b^\dagger] = 1$. (By identifying $a = a_k$ and $b = a_{-k}$, we can directly apply calculations here to those for the free scalar field for a fixed k sector.) Then we can explicitly write the state defined (45) as

$$|\psi_\lambda\rangle = \sqrt{1 - |\lambda|^2} \cdot e^{-\lambda a^+ b^+} |0\rangle, \quad (85)$$

where λ is related A_k and B_k via $\lambda = B_k/A_k$. Then the inner product is found to be

$$\langle \psi_{\lambda'} | \psi_\lambda \rangle = \frac{\sqrt{(1 - |\lambda|^2)(1 - |\lambda'|^2)}}{1 - \lambda'^* \lambda}. \quad (86)$$

By taking the limit $d\lambda = \lambda' - \lambda \rightarrow 0$, the quantum metric is computed as

$$ds_k^2 = \frac{d\lambda d\lambda^*}{(1 - |\lambda|^2)^2} = (A_k dB_k - B_k dA_k)(A_k^* dB_k^* - B_k^* dA_k^*), \quad (87)$$

where we used the relation $|A_k|^2 - |B_k|^2 = 1$. This metric (87) coincides with that of the two dimensional hyperbolic space or Euclidean AdS_2 .

4.3 Emergent Metric from cMERA

Now we consider the construction of the metric in the cMERA. Again we assume the translational symmetry in the x direction and would like to construct g_{uu} from the data in the cMERA. We argue that a natural definition of the metric component g_{uu} for static states in the cMERA is obtained by applying the quantum metric (83) in an appropriate way as described below. Since the Hilbert space of scalar field theory consists of the direct product of each sectors with fixed momentum k , finally we need to integrate over k . We define the metric g_{uu} in the cMERA as follows:

$$g_{uu}(u)du^2 = \mathcal{N}^{-1} \left(1 - \left| \langle \Psi(u) | e^{iL \cdot du} | \Psi(u + du) \rangle \right|^2 \right) = \mathcal{N}^{-1} \left(1 - |\langle \Phi(u) | \Phi(u + du) \rangle|^2 \right), \quad (88)$$

where we employed the relation (21). The normalization factor \mathcal{N} is given by the volume of the effective phase space at length scale u :

$$\mathcal{N} = \text{Vol} \cdot \int_{|k| \leq \Lambda e^u} dk^d, \quad (89)$$

where Vol is the (infinite) volume of d dimensional space R^d .

Notice that this measures the density of strength of the unitary transformations induced by disentanglers. To extract only the effect of disentanglers we need to get rid of the scale transformation (or coarse-graining) by putting the operator $e^{iL \cdot du}$ in (88). Comparing with (82), we have normalized the metric by the volume of the phase space at the scale u in the denominator so that the metric measures the density of the strength of disentanglers. Note that it is still possible to multiply any finite constant with the definition (88). This normalization turns out to be convenient when comparing the quantum metric in the MERA with the bulk background metric in AdS/CFT. Observe that (88) can be rewritten as⁶

$$g_{uu}(u) = \langle \Phi(u) | \hat{K}(u)^2 | \Phi(u) \rangle - \langle \Phi(u) | \hat{K}(u) | \Phi(u) \rangle^2. \quad (90)$$

The reasoning to identify the quantum metric (88) as a bulk (or holographic) metric is based on their relation to the entanglement entropy, as we discussed for the discrete MERA (see around (77)-(78)); when we choose the subsystem A to be the half of the total space, the disentanglers “cut” by the division γ_A of the MERA network, which is induced by the bipartitioning in defining the entanglement entropy, contribute to the entanglement entropy. The strength of the disentangler is a function of u . The quantum metric $\sqrt{g_{uu}}$ measures the density of the strength of disentanglers. On the other hand, in the classical gravity limit of AdS/CFT, the holographic formula (1) relates

⁶It would also be possible to introduce the metric as $g_{uu}(u)du^2 = \mathcal{N}^{-1} \left(1 - |\langle \tilde{\Psi}(u) | \tilde{\Psi}(u + du) \rangle|^2 \right)$ with $|\tilde{\Psi}(u)\rangle := U(0, u)|\Omega\rangle$. This definition of the metric leads to qualitatively similar results.

the area of the minimal surface (γ_A) and the entanglement entropy. These considerations support the identification (88) as the bulk metric.

In time-dependent states such as the ones obtained from the quantum quenches, we need to be careful to apply the formula (88) due to the ambiguity of the phase factor θ_k defined in (69) noted in previous section. More details of this will be discussed in the next subsection.⁷

Also we need to remember that the use of (1) is restricted to the case where we take the strongly coupling and large N limit of the CFT. In the free scalar field theory model where we perform detailed calculations, the dual gravity is expected to be highly quantum and the metric $\sqrt{g_{uu}}$ cannot be regarded as that of the classical Einstein gravity. Nevertheless, we can still propose that (88) always provides a metric which describes the dual geometry in a qualitative way. Indeed, as the calculations of the entanglement entropy in the 4D $\mathcal{N} = 4$ super Yang-Mills theory suggest [21], in some cases, the behavior of the entanglement entropy does not qualitatively change when we dial the coupling constant from zero to infinity. It would be an very interesting future problem to somehow explore the metric $\sqrt{g_{uu}}$ in strongly coupled large N gauge theories to see a direct connection to the Einstein gravity.

4.4 Coordinate Transformations and Time-Dependent Backgrounds

A very important question on the interpretation of AdS/CFT in terms of the cMERA is how the diffeomorphism invariance in the gravity is encoded in the cMERA. Even though we leave comprehensive understandings of this issue for future works, here we would like to try to present a schematic explanation. As we assumed in the formula (88), we impose the translation symmetry in \vec{x} direction for the states we consider.

First of all, we notice that the change of the cut off function $\Gamma(|k|e^{-u}/\Lambda)$ can be understood as a part of the diffeomorphism. This is because if we change $\Gamma(|k|e^{-u}/\Lambda)$ into $\Gamma(|k|\eta(e^{-u})/\Lambda)$, then this corresponds to the coordinate transformation $e^{-u} \rightarrow \eta(e^{-u})$ in the extra dimension.

Next, remember that there is an ambiguity of choices of the phase factor θ_k (69) in excited states as we noted in the previous section. Though the UV state $|\Psi\rangle$ is clearly independent of θ_k , the states $|\Psi(u)\rangle$ at intermediate energy scale depend on θ_k in general. Note that θ_k can be an arbitrary function of time t . It is tempting to argue that this ambiguity corresponds to the choices of time slices in the bulk gravity. The time slice $t = t_0$ in a quantum field theory just corresponds to the one at the boundary of the gravity dual (e.g., $z = 0$ in the AdS metric (75)), following the standard idea of holography. In the gravity dual, we need to extend the time slice at the boundary

⁷We present another definition of metric in appendix A. This is free from this ambiguity even though it can only be applicable to coherent states. This metric coincides with (88) if the function $g(u)$ is real.

into the bulk in order to find the gravity dual of a series of states $|\Psi(u)\rangle$. It is clear that there are infinitely different ways to do this extension. In a translationally invariant background, this bulk time slice at time t_0 is specified by $F(t, z) = t_0$ in terms of the bulk time t and radial coordinate $z(= \epsilon e^{-u})$, for a certain function F . The phase ambiguity $\theta_k(t)$ indeed has the same degree of freedom as $F(t, z)$ by roughly identifying $z = 1/k$. It is curious to notice that the ambiguity θ_k originally comes from the fundamental fact that the state or wave function in quantum mechanics is only defined up to a phase factor.

Now we would like to consider how we can apply the metric (88) to time-dependent states in the cMERA. For this, it is useful to remember the holographic calculations of the entanglement entropy in time-dependent backgrounds [27], where S_A is given by the area of extremal surface in the full Lorentzian spacetime instead of a minimal surface on a time-slice. By considering the case where A is a half space and the holographic calculation (78) as before, we can argue that the metric (88) leads to the correct metric in the gravity dual if we choose the phase $\theta_k(t)$ such that the extremal surface γ_A is on the corresponding time slice.

As a consistency check of the above argument, we can explicitly confirm that only for the ground states in free scalar field theories, the metric component (88) does not depend on the choice of θ_k . In this static case, the metric corresponds to the the most natural time slice $t = t_0$ in the coordinate (76).

4.5 Calculation of Metric in Free Scalar Field Theory

To calculate the metric $g_{uu}(u)$ explicitly, we focus on the free scalar field theory with a mass m . Let us consider a class of states which are given by the coherent states

$$(A_k(u)a_k + B_k(u)a_{-k}^\dagger)|\Phi(u)\rangle = 0, \quad (91)$$

where $A_k(u)$ and $B_k(u)$ are related to $M_k(u)$ via (59). By using (87), (59), (52) and (53), the metric is computed as

$$\begin{aligned} g_{uu}(u) &= \mathcal{N}^{-1} \int_{|k| \leq \Lambda e^u} d^d k [A_k(u)\partial_u B_k(u) - B_k(u)\partial_u A_k(u)] [A_k^*(u)\partial_u B_k^*(u) - B_k^*(u)\partial_u A_k^*(u)] \\ &= \mathcal{N}^{-1} \int_{|k| \leq \Lambda e^u} d^d k [A_k(u)^2 g(u) - B_k(u)^2 g^*(u)] [A_k^*(u)^2 g^*(u) - B_k^*(u)^2 g(u)], \end{aligned} \quad (92)$$

where \mathcal{N} was the normalization factor defined in (89).

Let us focus on the special case where $g(u)$ defined in (52) is real. Then (51) and (59) tell us that $M_k(u)$, $A_k(u)$ and $B_k(u)$ are also real valued. Under this assumption, the expression (92) is simplified as

$$g_{uu}(u) = g(u)^2. \quad (93)$$

4.5.1 Ground states

If we consider the ground state in the free scalar field theory, we find (93) leads to

$$g_{uu}(u) = \chi(u)^2 = \frac{e^{4u}}{4(e^{2u} + m^2/\Lambda^2)^2}. \quad (94)$$

We introduce a new coordinate z by

$$e^{2u} = \frac{1}{\Lambda^2 z^2} - \frac{m^2}{\Lambda^2}, \quad (95)$$

where $0 < z < 1/m$. Then the metric looks like

$$ds^2 = \frac{dz^2}{4z^2} + \left(\frac{1}{\Lambda^2 z^2} - \frac{m^2}{\Lambda^2} \right) dx^2 + g_{tt} dt^2. \quad (96)$$

This metric is capped off (vanishes) at $z = 1/m$ and this is consistent with the mass gap in the scalar field theory.

In the massless case $m = 0$, the spacial part of the metric (96) coincides with that of the pure AdS. Also for the Lifshitz-like critical theory, we can show that the metric g_{uu} is a constant as follows from (44). This is consistent with the proposed metric dual to Lifshitz-like fixed points [46].

4.5.2 Quantum Quenches

Now we would like to consider the time-dependent metric which corresponds to the excited state after a global quantum quench. The calculations get highly complicated as we need to specify the phase θ_k so that the time-slice coincides with the extremal surface γ_A as we explained. Here we would like to do a shortcut by fixing θ_k artificially. This is still enough to obtain qualitative behavior of the time-dependence of the metric. The metric can be obtained from the formula (93) by substituting (71) and (72).

First of all, it is clear from (71), the square root of the metric $\sqrt{g_{uu}} = g(u)$ in (88) grows linearly in time t . This agrees with the fact that the entanglement entropy increases linearly in time t after quantum quenches, which has been shown first for two dimensional CFTs in [41], and has been later obtained holographically in any dimensions in [47]. This offers a non-trivial evidence for our proposed metric (88).

Next let us look at Fig. 4 again. This is now interpreted as the plot of $\sqrt{g_{uu}}$ as a function of the radial coordinate $z(= 1/|k|)$ and t in the gravity dual. We can observe that the quantum quench induces the gravitational waves approximately within the light-cone $z < t$, which agrees with the causality in the bulk.

4.5.3 Towards Flat Space Holography

Let us assume the behavior

$$g_{uu}(u) = g(u)^2 \propto e^{2wu}, \quad (97)$$

where w is a constant. For a generic form of the dispersion relation $\epsilon = \epsilon_k$, we find the relation (42) between $g(u)$ and ϵ_k . Therefore the metric (97) corresponds to the dispersion relation

$$\epsilon_k \propto e^{A \cdot k^w}, \quad (98)$$

where A is a certain positive constant. This dispersion relation is unusual and is highly non-local. Indeed, the corresponding Hamiltonian looks like

$$H = \int d^d x \phi(x) e^{A(-\partial^2)^{w/2}} \phi(x). \quad (99)$$

The metric (76) with (97) becomes almost flat on a time slice if we choose $w = 1$. This corresponds to the Hamiltonian

$$H = \int d^d x \phi(x) e^{A\sqrt{-\partial^2}} \phi(x). \quad (100)$$

Notice that a very similar non-local field theory appears in [48] where a possible dual to gravity in flat space has been explored. A lesson we obtained here is that when we consider the holographic dual of the metric (97) with w non-vanishing, the dual theory is expected to be highly non-local.

5 Another example: Free Fermion in Two Dimensions

So far we have considered the free scalar field theory as an example. Here we would like to briefly show that similar calculations can be done for free fermions. The cMERA for the free fermion has been worked out in the version 1 of [33] and we follow almost the same convention. Readers who are interested in general discussions may skip this section and move on to the final section.

For simplicity, we focus on the free Dirac fermion ψ in $(1+1)$ dimensions, defined by the action

$$S_F = \int dt dx [i\bar{\psi}(\gamma^t \partial_t + \gamma^x \partial_x)\psi - m\bar{\psi}\psi], \quad (101)$$

where $\psi = (\psi_1, \psi_2)^T$ is the two-component complex fermion and γ matrices are defined by $\gamma^t = \sigma_3$ and $\gamma^x = i\sigma_2$ in terms of the Pauli matrices. Also we define $\bar{\psi} = \psi^\dagger \gamma^t$ as usual. The Hamiltonian of this theory is given by

$$\begin{aligned} H &= \int dx [-i\bar{\psi}\gamma^x \partial_x \psi + m\bar{\psi}\psi] \\ &= \int dk [k\psi_1^\dagger(k)\psi_2(k) + k\psi_2^\dagger(k)\psi_1(k) + m\psi_1^\dagger(k)\psi_1(k) - m\psi_2^\dagger(k)\psi_2(k)], \end{aligned} \quad (102)$$

where we performed the Fourier transformation. The canonical quantization leads to the following anti-commutation relation

$$\{\psi_1(k), \psi_1^\dagger(k')\} = \{\psi_2(k), \psi_2^\dagger(k')\} = \delta(k - k'). \quad (103)$$

5.1 cMERA for Free Fermion

The unentangled IR state can be defined by

$$\psi_1(k) |\Omega\rangle = 0, \quad \psi_2^\dagger(k) |\Omega\rangle = 0. \quad (104)$$

On the other hand, the true ground state $|\Psi\rangle$ of this free fermion theory is given by

$$\tilde{\psi}_1(k) |\Psi\rangle = 0, \quad \tilde{\psi}_2^\dagger(k) |\Psi\rangle = 0, \quad (105)$$

where $\tilde{\psi}_{1,2}$ is defined by

$$\begin{aligned} \tilde{\psi}_1(k) &= A_k^{(0)} \psi_1(k) + B_k^{(0)} \psi_2(k) \\ \tilde{\psi}_2(k) &= -B_k^{(0)} \psi_1(k) + A_k^{(0)} \psi_2(k), \end{aligned} \quad (106)$$

with

$$A_k^{(0)} = \frac{-k}{\sqrt{k^2 + (\sqrt{k^2 + m^2} - m)^2}}, \quad B_k^{(0)} = \frac{m - \sqrt{m^2 + k^2}}{\sqrt{k^2 + (\sqrt{k^2 + m^2} - m)^2}}. \quad (107)$$

These fermion operators satisfy the following commutation relations:

$$\begin{aligned} [H, \tilde{\psi}_1^\dagger(k)] &= \sqrt{k^2 + m^2} \tilde{\psi}_1^\dagger(k), \\ [H, \tilde{\psi}_2^\dagger(k)] &= -\sqrt{k^2 + m^2} \tilde{\psi}_2^\dagger(k). \end{aligned} \quad (108)$$

More generally we can consider the excited states defined by

$$\begin{aligned} (A_k \psi_1(k) + B_k \psi_2(k)) |\Psi\rangle &= 0, \\ (-B_k \psi_1^\dagger(k) + A_k \psi_2^\dagger(k)) |\Psi\rangle &= 0. \end{aligned} \quad (109)$$

We can normalize

$$|A_k|^2 + |B_k|^2 = 1. \quad (110)$$

Notice that the state $|\Psi\rangle$ does not change if we multiply a common phase factor to (A_k, B_k) as in the previous scalar field example. The choice $(A_k, B_k) = (A_k^{(0)}, B_k^{(0)})$ corresponds to the ground state.

As before, we aim to relate the UV state $|\Psi\rangle$ to the common IR state via the unitary transformation (19). We assume the following form for the disentanglers

$$\hat{K}(u) = i \int dk \left[g_k(u) \psi_1^\dagger(k) \psi_2(k) + g_k^*(u) \psi_1(k) \psi_2^\dagger(k) \right], \quad (111)$$

where the function $g_k(u)$ is chosen to be the form

$$g_k(u) = g(u)\Gamma(|k|e^{-u}/\Lambda)\frac{ke^{-u}}{\Lambda}. \quad (112)$$

where $g(u)$ is complex-valued in general. The presence of the factor k , which is missing in the scalar field theory, is now required to reproduce the correct ground state (107) as noted in [33].

In terms of the particle annihilation and anti-particle creation operators, we obtain

$$\begin{aligned} P e^{-i \int_{u_{\text{IR}}}^u \hat{K}(u') du'} \begin{pmatrix} \psi_1(k) \\ \psi_2(k) \end{pmatrix} \tilde{P} e^{i \int_{u_{\text{IR}}}^u \hat{K}(u') du'} &= M_k(u) \begin{pmatrix} \psi_1(k) \\ \psi_2(k) \end{pmatrix}, \\ P e^{-i \int_{u_{\text{IR}}}^u \hat{K}(u') du'} \begin{pmatrix} \psi_1^\dagger(k) \\ \psi_2^\dagger(k) \end{pmatrix} \tilde{P} e^{i \int_{u_{\text{IR}}}^u \hat{K}(u') du'} &= N_k(u) \begin{pmatrix} \psi_1^\dagger(k) \\ \psi_2^\dagger(k) \end{pmatrix}, \end{aligned} \quad (113)$$

where we introduced rank 2 matrices $M_k(u)$ and $N_k(u)$ as

$$\begin{aligned} M_k(u) &\equiv \begin{pmatrix} P_k(u) & Q_k(u) \\ -Q_k^*(u) & P_k^*(u) \end{pmatrix} = \tilde{P} \exp \left(\int_{u_{\text{IR}}}^u du' G_k(u') \right), \\ N_k(u) &\equiv \begin{pmatrix} P_k^*(u) & Q_k^*(u) \\ -Q_k(u) & P_k(u) \end{pmatrix} = \tilde{P} \exp \left(\int_{u_{\text{IR}}}^u du' H_k(u') \right), \end{aligned} \quad (114)$$

with $G(u)$ and $H(u)$ defined by

$$G_k(u) = \begin{pmatrix} 0 & -g_k(u) \\ g_k^*(u) & 0 \end{pmatrix}, \quad H_k(u) = \begin{pmatrix} 0 & -g_k^*(u) \\ g_k(u) & 0 \end{pmatrix}. \quad (115)$$

Equivalently, we can show that

$$\frac{dM_k(u)}{du} = M_k(u)G_k(u), \quad \frac{dN_k(u)}{du} = N_k(u)H_k(u). \quad (116)$$

The matrices $M_k(u)$ and $N_k(u)$ clearly satisfy $|P_k(u)|^2 + |Q_k(u)|^2 = 1$ and preserve both the commutation relation of $\psi_1(k)$ and $\psi_1^\dagger(k)$ and the one of $\psi_2(k)$ and $\psi_2^\dagger(k)$. By comparing the IR and UV states, we obtain the relation

$$P_k(0) = A_k(0), \quad Q_k(0) = B_k(0). \quad (117)$$

Notice that $M_k(u)$ and $N_k(u)$ satisfy

$$\begin{aligned} M_k(u)^\dagger M_k(u) &= \mathbf{1}, \quad \det M_k(u) = 1, \\ N_k(u)^\dagger N_k(u) &= \mathbf{1}, \quad \det N_k(u) = 1, \end{aligned} \quad (118)$$

which says these belong to $SU(2)$. Also the parametrization (115) covers only two out of three generators of $SU(2)$. Though the remaining one is found to be

$$e^{i\delta_k \sigma_3} \in SU(2), \quad (119)$$

we can ignore this by using the phase ambiguity of (109) as in the free scalar field theory case.

5.2 Ground State

If we assume that $g_k(u)$ takes only real values i.e. $g_k = (g_k)^*$, then we find from (115)

$$M_k(u) = N_k(u) = \begin{pmatrix} \cos \left(\int_{u_{\text{IR}}}^u du' g_k(u') \right) & -\sin \left(\int_{u_{\text{IR}}}^u du' g_k(u') \right) \\ \sin \left(\int_{u_{\text{IR}}}^u du' g_k(u') \right) & \cos \left(\int_{u_{\text{IR}}}^u du' g_k(u') \right) \end{pmatrix}. \quad (120)$$

By comparing between these at the UV point $u = 0$, we find

$$\sin 2\varphi_k = \frac{-k}{\sqrt{k^2 + m^2}}, \quad (121)$$

where we defined

$$\varphi_k = \int_{\log|k|/\Lambda}^0 du g(u) \frac{ke^{-u}}{\Lambda}. \quad (122)$$

The function $g(u)$ is found from (122) as follows

$$g(u) = -\frac{k|k|}{\Lambda} \frac{\partial}{\partial k} \left[\frac{\Lambda}{k} \varphi_k \right] \Big|_{|k|=\Lambda e^u} = \frac{1}{2} \left[-\arcsin \frac{\Lambda e^u}{\sqrt{\Lambda^2 e^{2u} + m^2}} + \frac{m\Lambda e^u}{m^2 + \Lambda^2 e^{2u}} \right]. \quad (123)$$

In particular, in the massless case $m = 0$ we find that $g(u)$ becomes a constant

$$g(u) = \varphi_k = -\frac{\pi}{4}. \quad (124)$$

5.3 Metric from cMERA

Now we would like to move on to a holographic interpretation of the cMERA in this free fermion theory. We can apply the general formula (88) for the metric in the extra dimension. The state defined by (109) is written as the coherent state

$$|\psi_\lambda\rangle = \frac{[1 - \lambda \psi_1^\dagger(k) \psi_2(k)]}{\sqrt{1 + |\lambda|^2}} |\Omega\rangle, \quad (125)$$

where $\lambda = \frac{B_k}{A_k}$. We can show

$$\langle \psi_{\lambda'} | \psi_\lambda \rangle = \frac{1 + \lambda \lambda'^*}{\sqrt{(1 + |\lambda|^2)(1 + |\lambda'|^2)}}. \quad (126)$$

By considering an infinitesimal Bures distance (or equally Hilbert-Schmidt distance), we find the corresponding metric. If we take the limit $\lambda' \rightarrow \lambda$,

$$\begin{aligned} D_B(\psi_{\lambda'}, \psi_\lambda) &= \lim_{\lambda' \rightarrow \lambda} 2(1 - |\langle \psi_{\lambda'} | \psi_\lambda \rangle|) = \frac{d\lambda^* d\lambda}{(1 + |\lambda|^2)(1 + |\lambda'|^2)} \\ &= (A_k^* dB_k^* - B_k^* dA_k^*)(A_k dB_k - B_k dA_k) \end{aligned} \quad (127)$$

Finally the holographic metric (88) is found to be

$$\begin{aligned} g_{uu}(u) &= \frac{1}{\mathcal{N}} \int_{|k| \leq \Lambda e^u} dk [A_k(u)^* \partial_u B_k(u)^* - B_k(u)^* \partial_u A_k(u)^*] [A_k(u) \partial_u B_k(u) - B_k(u) \partial_u A_k(u)] \\ &= \frac{1}{\mathcal{N}} \int_{|k| \leq \Lambda e^u} dk \left(\frac{k^2 e^{-2u}}{\Lambda^2} \right) [A_k^2(u) g(u) + B_k(u)^2 g(u)^*] \cdot [A_k^*(u)^2 g(u)^* + B_k^*(u)^2 g(u)], \end{aligned}$$

where \mathcal{N} is defined in (89). When $g(u)$ is a real valued function, we find

$$g_{uu}(u) = \frac{g(u)^2}{3}. \quad (128)$$

For the ground state (124) of massless fermion theory, we can find that g_{uu} is a constant and the gravity dual becomes a AdS space as expected from the conformal symmetry.

6 Conclusions and Discussions

By making use of the holographic formula for the entanglement entropy as a hint, we have introduced a proper metric to the MERA tensor networks and in particular to their continuum counter parts in the cMERA. The metric captures how quantum degrees of freedom are entangled with each other at different length scales. We computed the metric explicitly for the cMERA for free boson and free fermion quantum field theories. We have checked that the computed metric has properties expected from the holography; that it coincides with the AdS metric when these field theories are conformal field theories; that it is capped off when there is a mass gap; that its square root grows linearly in time after quantum quench, etc.

Our formulation based on the cMERA can be applied to holography for wide classes of spacetimes which are far more general than the AdSs. For example, we found that if we consider holographic duals of generic spacetimes such as a flat spacetime, they should be highly non-local theories including infinitely many derivatives in their Hamiltonians. It might be an interesting future problem to understand the physics of black holes in a flat spacetime by using this formulation. For example, they have the intriguing properties such as the negative specific heat. Interestingly, it has been known that the negative specific heat can happen in highly non-local theories [49]. Also it is another important future problem to extend our formulation to the finite temperature theories dual to AdS black holes (refer to the recent paper [13] for a construction of black hole states in MERA based on the thermofield dynamics).

In the interpretation of the cMERA as AdS/CFT, the key identification is that each of entangling bonds (disentangled) in an appropriate time slice can be regarded as a unit surface area. It is very exciting to note that this correspondence seems to be naturally generalized to spacetimes which have no space-like boundaries and which do not follow the standard rule of holography. This

Figure 7: A conceptual sketch of a possible formulation of quantum gravity in terms of entanglement.

might offer us a hint to formulate quantum gravity in general spacetimes (see Fig. 7). Notice that in this correspondence, both sides are manifestly dynamical because the time coordinate is already built in and cannot be emergent. Refer to [7, 42] for closely related ideas which connect the quantum entanglement to the emergence of gravity dynamics.

A precise connection between the MERA and AdS/CFT is still missing, though. Firstly, in our current approach, we could not determine the time component of the holographic metric. In other words, our metric is the one on a fixed time slice and this depends on the choice of the time slice. In principle we can boost the system and calculate the entanglement entropy so that we can read off the time component of metric. This certainly deserves future studies. Secondly, the role of the large N limit in the MERA is not clear yet (although we gave a speculation on this point). On the other hand, the non-necessity of the large N limit in formulating the MERA can be thought of as an advantage; our metric can, in principle, be defined for arbitrary quantum many-body systems once their (ground) states are expressed in terms of the MERA tensor networks. Assuming that the MERA (and its suitable modification) can be applied to a wide class of quantum many-body problems, we can define a sort of bulk geometry averaged by quantum fluctuations for a wide class of systems. It is also useful to note that the gravity dual of $O(N)$ scalar field theory is given by the higher spin gravity [50] as has been recently studied actively [51, 52, 53, 54, 55]. We will be able to employ this correspondence to study the relation between the cMERA and AdS/CFT more closely. The excitations of higher spin fields will correspond to the addition of non s-wave terms to the disentanglers \hat{K} in (32).

This mysterious connection between the MERA and AdS/CFT opens up a possibility to classify various phases and states in quantum many-body systems in terms of their bulk geometry. This may be a good news, since there is growing evidence that quantum phases and quantum phase transitions cannot fully classified in terms of the conventional tools in classical statistical physics,

such as the Landau-Ginzburg type theories of phase transitions [56]. In the latter, classical phases can be characterized by a pattern of symmetry breaking, i.e., in terms of group theory. On the other hands, there are known examples that do not fall into this category; Most notably, topological phases of matter such as the fractional quantum Hall effect. AdS/CFT and the MERA offer an emerging holographic view for quantum phases, which is complementary to the Landau-Ginzburg paradigm, viz, quantum phases are to be classified by their emergent geometry.

In order to offer further evidence for the connection between AdS/CFT and the MERA (“AdS/MERA” in short), it is worth while mentioning and comparing how topological phases are represented in the MERA and AdS/CFT. (Fig. 8.) In [57], the MERA for a topologically ordered phase in two spatial dimensions is constructed for a particular lattice model, the Kitaev’s toric code model. One of the salient feature of the MERA tensor network for the toric code model is the existence of its “top tensor”, which is located at the most IR region (“top”) of the tensor network. The top tensor stores information on the topological degrees of freedom (or topological order). In particular, it captures one of the defining properties of the topological phases, the topological ground state degeneracy when the system is put on the Riemann surface of genus $g \geq 1$ (the ground state degeneracy is four in the toric code model on the torus). The tensor networks for the four ground states of the toric code are largely identical except in their top tensor.

On the other hand, in [58], the gravity dual of a three dimensional gauge theory which flows in the IR to the pure $SU(N)$ Chern-Simons theory is constructed. The geometry is capped off at IR since the theory is gapped. In addition, D7-branes are located at IR. This setup is gapped even without the D7-branes, but their presence is necessary to realize a topological phase; the D7-branes give rise to the Chern-Simons term, and contributes to the topological entanglement entropy. The holographic views of topological phases offered from the MERA and AdS/CFT are surprisingly similar, and it is tempting to identity the top tensor and the D7-branes.

Acknowledgements

A Another Definition of Metric for Coherent States

Here we discuss an intuitive measure of entanglement and based on this we would like to define another metric for the coherent states in the free scalar field theory. We consider the relative distance between the IR vector (α_k, β_k) defined in (28) and UV one (A_k, B_k) defined in (45). By performing the $SU(1,1)$ transformation, this is equivalent to the distance between $(1,0)$ and $(A_k\alpha_k - B_k\beta_k, \alpha_k B_k - \beta_k A_k)$. Notice that in the UV limit $k = M$, the distance is vanishing. If the distance is small for finite k , then the UV state $|\Psi\rangle$ is closer to the unentangled IR state $|\Omega\rangle$. Therefore this distance presents the measure of entanglement.

Now we parameterize

$$\begin{aligned} A_k \alpha_k - B_k \beta_k &= \cosh a_k \cdot e^{ib_k}, \\ \alpha_k B_k - \beta_k A_k &= \sinh a_k \cdot e^{ic_k}. \end{aligned} \quad (129)$$

The natural metric of this parameter space which preserves $SU(1, 1)$ structure is defined by

$$ds^2 = da^2 - \cosh^2 a db^2 + \sinh^2 a dc^2, \quad (130)$$

which coincides with the AdS_3 as is expected from the $SU(1, 1)$ symmetry. Moreover, we need to take a quotient by the identification $(b, c) \sim (b, c) + (\theta, \theta)$ for any θ , which is the phase ambiguity of the definition (45). In the end, we obtain the following AdS_2 metric

$$ds^2 = da^2 + \cosh^2 a \sinh^2 a (db - dc)^2, \quad (131)$$

and indeed it coincides with the quantum distance (87).

The vector (a_k, b_k, c_k) for $0 < k < M$ makes a trajectory Γ_Ψ in this AdS_2 space. For simplicity we start with a scalar field theory in $1 + 1$ dimension. The entanglement entropy S_A for a given subsystem A should be a functional of Γ_Ψ . A simplest choice will be just the length of Γ_Ψ .

The length L_k of this trajectory is defined by

$$L_k = \int_0^k dk \sqrt{(\partial_k a_k)^2 + \cosh^2 a_k \sinh^2 a_k (\partial_k b - \partial_k c)^2}. \quad (132)$$

L_k describes how the entanglement is added as we increase the energy scale k . Therefore we are lead to identify

$$\sqrt{g_{uu}^E} = k \frac{dL_k}{dk} = k \sqrt{(\partial_k a_k)^2 + \cosh^2 a_k \sinh^2 a_k (\partial_k b - \partial_k c)^2}, \quad (133)$$

assuming the relation $k = \Lambda e^u$. This defined a natural metric component g_{uu}^E in the extra dimension u .

Below we study the property of this metric in the massless free scalar theory $m = 0$. For the vacuum state $|\Psi\rangle$ i.e. $(A_k, B_k) = (1, 0)$, we simply find $g_{uu}^E = \frac{1}{4}$. Moreover, if $g(u)$ defined in (52) is real, we can show after some algebras

$$g_{uu}^E = g(u)^2 = g_{uu}. \quad (134)$$

Thus it agrees with the emergent metric defined in (88). However, in general excited states this equivalence is no longer true.

It is also interesting to note that for the ground state $|\Psi\rangle$ i.e. $(A_k, B_k) = (1, 0)$ we find

$$L_{tot} \equiv L_{k=M} = \frac{1}{2} \int_{\epsilon_{IR}}^M \frac{dk}{k} = \frac{1}{2} \log \left(\frac{M}{\epsilon_{IR}} \right), \quad (135)$$

Figure 9: Plots of $\sqrt{g_{uu}^E}$ as a function of t . In the left graph we assume $z = 1$, while the right one $z (= 1/k) = 10$. We assumed that $m_0 = 10$ and $m = 0$ for this quantum quench.

where ϵ_{IR} is the IR cut off. This is proportional to the entanglement entropy S_A in two dimensions (i.e. $d = 1$) when A is the half of the total space R^d .

In general, we can express such a functional of Γ_Ψ which is invariant under $SU(1, 1)$ symmetry as

$$S_A = \int_{\Gamma_\Psi} dk f(k) \sqrt{G_{AdS2}}, \quad (136)$$

for any function $f(k)$, where G_{AdS2} is the metric (131). If we assume that A is given by a half space of R^d , then the calculation should not depend on the energy scale i.e. k . Thus we can set $f(k)$ is a constant. This indeed agrees with the observation (135). On the other hand, when A is a strip with a finite width l , we will need to choose $f(k)$ is some function of the form $f(k) = F(kl)$. To extend this argument to higher dimensions d , we just need to multiply the degeneracy factor $e^{(d-1)u}$ in front of (136).

Also we would like to analyze the global quantum quench where the mass of the free scalar changes from m_0 to $m = 0$. We plotted the time evolution of $\sqrt{g_{uu}^E}$ for fixed values of z in Fig.9. This behavior is clearly consistent with the linear growth of the entanglement entropy. We can also confirm that the plot $\sqrt{g_{uu}^E}$ as a function $z = 1/k$ and t looks very similar to Fig.4. We can again qualitatively confirm that the excitations are propagating within the light-cone $z < t$.

Finally notice that this definition of metric does not have any ambiguity due to the phase factor as opposed to the one (88) we proposed in the main text. However, g_{uu}^E cannot be defined for general states as we employed the special property of coherent state that the state is written as the direct product of different momenta.
